Recent increase in detection of alprazolam in Victorian heroin-related deaths

The use of benzodiazepines by opioid-dependent people is widespread.1,4 The 2011 Victorian Illicit Drug Reporting System (IDRS), a sentinel survey of people who inject drugs (PWID), reported 92% lifetime and 71% recent (in the past 6 months) use among PWID.5 PWID use benzodiazepines for a number of reasons: to enhance the intoxicating effects of heroin or other opioids, manage anxiety, or manage withdrawal symptoms.3

The contribution of benzodiazepines to heroin overdose is well established.5-7 Alprazolam is a benzodiazepine registered in Australia for short-term treatment of anxiety and panic disorder. It is not recommended as first-line treatment because of concerns about risks of dependence and its potential for misuse.4,6

Alprazolam, like other commonly misused drugs, has a rapid onset and offset of action and high potency.3 Alprazolam may also be more toxic in overdose than other benzodiazepines.9 Laboratory-based studies have found that in combination with methadone, alprazolam has significant effects on respiration.10 A review of the interaction concluded that most evidence suggests the interaction is pharmacodynamic in nature.11

Recent IDRS reports showed recent alprazolam use increased from 8% in 200512 to 69% in 2011.5 Alprazolam is now the most commonly injected benzodiazepine,5 with a reported street price of three tablets for $10.13 Alprazolam use is associated with disproportionate levels of harm, including amnesia, violent outbursts of rage in otherwise non-violent individuals, and theft.1,13-15 In Victoria, most alprazolam (81%) used by PWID in 2011 was obtained from illicit sources.5

Given the increased number of episodes of serious harm associated with alprazolam use, we aimed to examine its public health impact, to inform prescribing and to guide appropriate policy responses. We investigated trends in alprazolam prescribing and its detection in heroin-related deaths (HRDs) in Victoria. Our hypothesis was that increased mean consumption of alprazolam is likely to have significant effects on heroin users,6 a population already vulnerable to drug toxicity.

Methods

Victorian prescription estimates

Estimates of prescription numbers for all dose formulations of alprazolam dispensed in Victoria for each calendar year, 1990–2010, were calculated from national supply data, Australian Statistics on Medicines (ASM), published by the Pharmaceutical Benefits Advisory Committee Drug Utilisation Sub-Committee. We determined the annual proportion of Pharmaceutical Benefits Scheme (PBS) supply to Victoria using data from Medicare Australia and applied this proportion to the annual ASM data. The ASM data provide a more complete estimate of alprazolam supply, as they include both private non-PBS prescriptions (those that do not attract a PBS subsidy) and PBS prescription numbers.

A defined daily dose per 1000 population per day (DDD/1000/day) for Victoria was calculated for each year using the same Victorian proportions derived from the PBS figures, the DDD for alprazolam (1 mg),17 the base number of estimated alprazolam prescriptions in Victoria, the usual pack size (50 tablets) for each dose formulation and Victorian population data.

Alprazolam detection in heroin-related deaths

Annual aggregate numbers of HRDs and annual numbers of cases of HRD in which alprazolam was detected were extracted from the Victorian Institute of Forensic Medicine toxicology database. Cases reported to the Victorian coroner in the 21-year period 1990–2010 that were classified as drug-related deaths, involved heroin and had been subjected to toxicology testing were included. All cases had results for a full range of toxicology tests, including for ethanol and common drugs of misuse. All presumptive detections had been confirmed by appropriate analytical techniques. Alprazolam had been tested for, using both immunoassay class tests on urine or blood (depending on availability of specimens) and gas chromatography–mass spectrometry on blood. All detections had been confirmed and quantified in blood using validated methods.
Ethics approval was granted by the Victorian Institute of Forensic Medicine Research Advisory Committee.

**Statistical analysis**

We used a Poisson regression model to assess the relationship between estimated trends in alprazolam supply and HRDs involving alprazolam. All statistical tests adjusted for annual fluctuations in HRDs. Data were analysed using Stata, version 11 (StataCorp).

**Results**

**Alprazolam prescribing**

Alprazolam supply increased by 1426% from 0.42 DDD/1000/day in 1990 to 6.41 DDD/1000/day in 2010 (Box 1). The estimated number of Victorian prescriptions for alprazolam increased by 611%, from 609/100 000 population in 1990 to 3488/100 000 population in 2010 (Box 1). The most remarkable change was in prescriptions for the 2 mg formulation, which increased from 4.1% to 27.9% of the population-adjusted rate for alprazolam prescriptions between 1998 and 2010. Box 2 shows trends in total DDD/1000/day for the four alprazolam dose formulations. A large proportion of alprazolam prescriptions were private; in 2009, private prescriptions accounted for 37.2% of all prescriptions.

**Heroin-related deaths**

There were 2392 HRDs in Victoria from 1990 to 2010. The annual number varied considerably over this time, with a large increase in HRDs per year from 1993, peaking at 362 deaths in 1999 (Box 1). A large decrease in HRDs reflected a reduction in heroin supply in 2001, and numbers subsequently fluctuated between 26 and 76 HRDs per year from 2001 to 2009, increasing to 96 in 2010 (Box 1, Box 3).

The number of alprazolam detections increased steadily from 2004, reaching a peak in 2010. Detection fluctuated between 0 and 4.4% of HRDs from 1990 to 2004, with a large increase from 5.2% in 2005 to 35.3% in 2009, decreasing to 28.1% in 2010 (Box 1, Box 3).

The Poisson regression model showed that for every 1 unit increase in DDD/1000/day, HRDs involving alprazolam increased at an incidence rate ratio of 2.4 (95% CI, 2.1–2.8; P < 0.001). Box 4 shows a log linear relationship between supply and the proportion of HRDs in which alprazolam was detected.

**Discussion**

Our study over the 21 years from 1990 to 2010 showed a number of interesting trends in alprazolam prescribing and supply and its relationship to HRDs in Victoria. First, the supply of alprazolam increased despite its status as a second-line treatment for its approved indications; second, the increase in the supply of the high-dose formulation was disproportionate to the increase in other formulations; and third, the rate of detection of alprazolam in HRDs increased more rapidly after 2005, concurrently with other reports of increasing harm among PWID. The association between the detection of alprazolam in HRDs and alprazolam supply was strong and significant. While alprazolam may be more toxic in overdose than other benzodiazepines, the accelerated rate of detection in this population since 2005 could reflect an increased preference for and use of alprazolam, particularly the high-dose formulation, among heroin users.

This raises questions about the increased prescribing of a drug not preferred for treatment of its primary indication, and for which little evidence exists for effectiveness beyond short-term use. This is especially important given that it may be more toxic in overdose.
The number of HRDs has remained fewer than during the heroin glut in the late 1990s, which led to the peak in deaths shown in 1999. The lower numbers are likely to reflect trends in heroin supply and should not be interpreted as evidence that alprazolam is relatively safe.

A relative strength of our study is the reporting of all Victorian HRDs spanning a 21-year period, enabling the identification of long-term trends in alprazolam used shortly before death. These data provide valuable information for the future prevention of deaths among people who use heroin. In addition, the prescription data and DDD calculations are estimates of the total number of prescriptions dispensed, based on data from the ASM and Medicare. Incorporating the ASM data improves the accuracy of total prescription volume through the inclusion of private prescriptions.

The finding of a strong and statistically significant association between detection of alprazolam in cases of HRD and its supply in the community is useful for generating a hypothesis about possible causes of increasing detection of this drug in cases of HRD. However, this does not mean a causal relationship exists between the increasing alprazolam supply and such deaths. The contribution of alprazolam to deaths involving multiple drugs is difficult to determine, and it is therefore not possible to specify the proportion of cases of drug toxicity due to combined drugs where alprazolam contributed directly to death. We used detection of alprazolam as an indication of use by PWID, rather than contribution to death per se.

The absolute number and rate of cases of HRD in which alprazolam was detected has increased substantially since 2005. Concern about the misuse of alprazolam in 2010 led to a request to the Australian National Drugs and Poisons Schedule Committee to reschedule it to the more restrictive Schedule 8. Among the committee’s stated reasons for not doing so at that time was that there was insufficient evidence of a problem.

This study provides further evidence of the increasing problem, perhaps involving high-dose formulations, of use of diverted medications among PWID. Given the growing concerns with alprazolam use among PWID and its increasing involvement in HRDs, supply control measures — such as better monitoring and surveillance (including real-time prescription monitoring), rescheduling to Schedule 8, and education of health professionals — are warranted. Provision of information about the risks of concurrent use of opioids and alprazolam to PWID is also essential.
