Recent advances in type 1 diabetes

Type 1 diabetes (T1D) affects around 120 000 Australians, half of whom are diagnosed in adulthood. It is caused by the immune-mediated destruction of pancreatic beta cells, leading to insulin deficiency, hyperglycaemia and the risk of ketoacidosis. Antibodies directed against the beta-cell antigens insulin, glutamic acid decarboxylase 65 (GAD65), insulinoma-associated protein 2 (IA-2) and zinc transporter 8 (ZnT8) are markers of T1D autoimmunity used to confirm the diagnosis of T1D and to identify normoglycaemic people at high risk of progressing to T1D. The incidence of T1D has doubled in Australia during the past 20 years, leading to speculation that it is caused by environmental or epigenetic factors. Environmental changes that may play a pathogenic role include viral infections, a more hygienic environment, and increased caloric intake with associated weight gain.

Some individuals with insulin deficiency presenting as T1D do not express the typical beta-cell autoantibodies, and alternative diagnoses, such as early-onset type 2 diabetes or idiopathic (type 1b) diabetes, should be considered. Another possibility is monogenic diabetes, particularly in children with a strong family history and unusual clinical features, such as renal impairment or exocrine pancreatic insufficiency.

General management principles

Since the 1990s, the most common treatment strategy has been the combination of once- or twice-daily injections of long-acting insulin (eg, insulin detemir or glargine) and short-acting insulin (eg, neutral insulin or the aspart, lispro and glulisine insulin analogues) taken with meals. An individual’s required dose of long-acting (basal) insulin is relatively constant, but can vary with exercise and physiological stressors, such as illness. Glargine and detemir insulin are commonly preferred to NPH (neutral protamine Hagedorn) insulin because their use is associated with lower rates of nocturnal and severe hypoglycaemia. Detemir is also associated with less weight gain than insulin NPH. All three long-acting insulins achieve similar reductions in glycaemic haemoglobin (HbA1c) levels. Novel ultralong-acting insulin analogues are being developed. Insulin degludec provides basal insulin coverage for more than 40 hours, and achieves similar glycaemic control with less overnight hypoglycaemia than glargine. Degludec is approved for use in Europe, but is yet to be approved by the United States Food and Drug Administration or the Australian Therapeutic Goods Administration.

Bolus (meal-time) insulin requirements in T1D are more variable than basal insulin requirements, depending primarily on carbohydrate intake. Accordingly, many people with T1D learn to determine the carbohydrate content of their meals (“carbohydrate counting”) to guide their prandial insulin dose. Studies of advanced carbohydrate counting in T1D suggest that it reduces HbA1c levels and the frequency of hypoglycaemia.

Ideally, people with T1D learn to self-adjust their bolus insulin dose to achieve optimal glycaemic control, using calculations based on personal experience and clinical observation. The specific formulas, incorporating the insulin-to-carbohydrate ratio and the insulin sensitivity factor, are provided in the Box. Self-adjustment of insulin dose can be learned informally or during structured training courses, such as the Dose Adjustment for Normal Eating (DAFNE) program (www.dafne.org.au). Central to self-adjustment of insulin dose is the self-monitoring of blood glucose levels. This requires a minimum of four glucose checks each day: once before each meal, and at bedtime. Glucose checks 2 hours after a meal can also be used to assess the adequacy of the bolus insulin dose for the preceding meal.

Variability in both insulin absorption after subcutaneous injection and of carbohydrate absorption from the gut can contribute to glycaemic variation in T1D. Areas of lipohypertrophy that can result from repeated insulin
Bolus insulin self-titration calculation

- Carbohydrate ratio (CHR): grams of carbohydrate covered by 1 unit of insulin.
- Insulin sensitivity factor (ISF): drop in blood glucose level (in mmol/L) achieved by each unit of insulin.

Sample calculation:

- Tim has T1D. His CHR is 10 : 1 and his ISF is 2 : 1.
- He is about to have a lunch that includes 50 g of carbohydrate.
- His current blood glucose level (BGL) is 14 mmol/L. His target BGL is 6 mmol/L.
- Prandial insulin dose = carbohydrate load ÷ CHR or 50 g ÷ 10 = 5 units of insulin to cover the carbohydrate in the meal.
- Correctional insulin dose = variance from target glucose ÷ ISF or (14 − 6) ÷ 2 = 4 units of insulin to correct BGL from 14 mmol/L to 6 mmol/L.
- He should therefore take 9 units of short-acting insulin with his meal.

injections at the same site may further impair insulin absorption. Development of lipohypertrophy is less likely if the injection site is rotated regularly.

Exercise and illness are also potent modifiers of glycaemia. The acute glycaemic effects of exercise can vary according to the intensity of physical activity, but there is generally a tendency to delayed hypoglycaemia and a reduced insulin requirement.

All individuals should have a thorough knowledge of sick-day management, including more frequent glucose monitoring, ketone testing, self-adjustment of insulin dose, maintaining oral intake of food and liquid, and having a low threshold for seeking medical attention.

As with any chronic disease, psychosocial factors strongly influence T1D self-management. An individual may fluctuate between active management and total disengagement, depending on social circumstances and psychological factors, such as anxiety and depression.

Health care providers should recognise these challenges. Taking social factors into account, referring people with T1D to appropriate psychological services, and gently helping the individual re-engage with self-care usually achieves better outcomes than focusing only on medical management.

Hypoglycaemia is a common and often a feared adverse event that is a major barrier to attaining near-normal blood glucose levels. Adults with T1D experience, on average, two mild hypoglycaemic episodes each week. More severe hypoglycaemia (requiring external assistance for recovery) occurs with an annual prevalence of 30%. The risk of hypoglycaemia increases with the duration of disease and is inversely correlated with HbA1c levels. Hypoglycaemia is a recognised cause of seizure and coma, and recent evidence suggests it may also cause serious cardiac ischaemia and arrhythmia. In addition, recurrent severe hypoglycaemia in children with early-onset T1D is associated with lower cognitive test scores in adulthood. Severe hypoglycaemia and hypoglycaemic unawareness also underlie diabetes-related distress and poorer emotional well-being. Glycaemic targets should therefore be individualised, and must always be balanced against the risk of hypoglycaemia. It is encouraging that the incidence of severe hypoglycaemia in a cohort of Australian children with T1D has decreased over the past decade from 17.3 to 5.8 per 100 patient-years.

New technologies that assist with glucose control

There has been an explosion in the availability of new technologies that assist the self-management of T1D. New blood glucose meters are more convenient than older models, with streamlined electronic data upload and connectivity to health care teams. Blood glucose meters that include a built-in bolus dose calculator (also called “smart meters”) integrate the insulin-to-carbohydrate ratio and insulin sensitivity factor when calculating insulin doses for each meal. There is, however, no strong evidence for improved glucose control in individuals using these devices. Several smartphone applications are now available to assist with various aspects of self-management, including carbohydrate counting, glucose monitoring and insulin dose calculations.

Insulin pumps are becoming increasingly popular, and are used by about 10% of Australians with T1D. Insulin pumps deliver short-acting insulin through a subcutaneous cannula that the patient re-positions every 3 days. Insulin is delivered continuously, and the rate can be varied to better mimic endogenous insulin production and to match physical activity. Prandial and correctional insulin boluses are administered via the pump under the control of the user. Compared with multidose insulin therapy, pump therapy is associated with a reduction in HbA1c levels of about 3.3 mmol/mol (0.3%), but, more importantly, also with reduced rates of severe hypoglycaemia and improved quality of life. However, their safe and successful operation requires the close engagement of the individual with their pump, their willingness to undertake adequate glucose monitoring, and their proficiency in carbohydrate counting. Insulin pumps cost up to $9500, which can generally be partially or fully reimbursed by private health insurers; the government provides a subsidy for children from low-income families.

Continuous glucose monitoring systems measure interstitial fluid glucose concentrations every 5 minutes via a thin glucose-sensing subcutaneous cannula. Continuous glucose monitors can be used in individuals with T1D for a week at a time to retrospectively assess the 24-hour blood glucose profile and to diagnose unrecognised hypo- and hyperglycaemia. They can also be employed for longer periods, together with an insulin pump, to provide real-time glucose readings. These sensor-augmented pumps enable individuals to adjust insulin doses in response to glucose level trends, and to safely reduce HbA1c levels by about 3.3 mmol/mol (0.3%). Sensor-augmented pumps also incorporate a “low-glucose-suspend” feature that temporarily stops insulin

**Prospects for the prevention of T1D**

The ability to predict T1D on the basis of genetic, immunological and metabolic markers has provided opportunities for prevention at different preclinical stages. Most attention has focused on interventions at diagnosis, a stage when significant amount of endogenous insulin is still produced. Treatment with anti-CD3, anti-CD20 or abatacept have shown clear promise and may be employed in the future to preserve beta-cell function. Trials are also underway investigating strategies that prevent T1D in high-risk populations characterised by detectable islet autoantibodies but with normal glucose tolerance. The intranasal insulin trial, led by an Australian team but including additional New Zealand and German sites, for instance, is examining whether a 12-month course of nasal insulin vaccine is an effective prevention strategy (https://clinicaltrials.gov/ct2/show/NCT00336674). An even more experimental strategy would be to prevent people with an elevated genetic risk from developing autoimmunity, a process that usually commences in utero and during the first few years of life. Central to this effort will be identifying the environmental triggers of autoimmunity, a question being investigated by the Environmental Determinants of Islet Autoimmunity Study.30

**T1D cure with pancreas or islet transplantation**

Whole pancreas transplant, usually performed simultaneously with a kidney transplant in people with T1D and renal failure, is a well-established therapy at the Westmead National Pancreas Transplant Unit in Sydney and the Monash Medical Centre in Melbourne. This procedure normalises blood glucose levels without requiring exogenous insulin, and also partially repairs established nephropathy, retinopathy, vascular disease and hypoglycaemic unawareness. Pancreatic graft survival is estimated to be greater than 60% at 5 years, but the benefits must be weighed against the surgery and associated immunosuppression.31

The concept of transplanting the islets of Langerhans to cure T1D was proposed more than 30 years ago, and remains an attractive but logistically difficult long-term solution. In Australia, islet isolation is undertaken at Westmead Hospital in Sydney and at St Vincent’s Hospital in Melbourne, and transplants are performed at these centres and at the Royal Adelaide Hospital. Islet transplants are offered to those who have life-threatening hypoglycaemia; 44% of recipients still did not require insulin 3 years after transplant (usually an endovascular procedure, not a surgical procedure). These benefits come, again, at the expense of lifelong immunosuppression and its attendant risks.32 Limited tissue supply is a key barrier to more widespread use of islet transplantation. Advances in stem-cell technologies or in the production of porcine islets for human transplant may overcome this problem in the future.

**Prognosis in T1D**

Despite recent advances, T1D is still associated with considerable premature mortality caused by acute and chronic complications, particularly ischaemic heart disease.33 The presence and severity of chronic kidney disease and ischaemic heart disease predict all-cause mortality in T1D.34,35 Recent reports of improved life expectancy in the US36 and in Denmark37 nonetheless provide great hope for persons with T1D and their clinicians.
